ABSTRACT

Introduction: Stroke is one of the leading causes of morbidity and mortality worldwide with age-adjusted prevalence rate of stroke was between 250-350/100,000 in India accounting for 1.2 % of total deaths. Atherosclerotic plaque at the carotid bifurcation is a major cause of ischemic strokes. Study aimed to evaluate the imaging appearances of atheromatous plaque using Ultrasound and MRI.

Material and methods: Sonographic images to be evaluated for Plaque at bifurcation and was classified as homogenous or heterogeneous with proper surface evaluation for irregularity. MRI of the carotids was done and the visualised plaque were grouped into homogenous and heterogeneous categories which in turn were correlated with ultrasound pictures to characterize the type of plaque. The plaque characteristics were then compared with the clinical condition of the patient to compare its relation with the incidence of stroke or TIA.

Results: Ultrasound was found to be more sensitive than MRI for plaque size < 1.5mm and to characterize when the area of stenosis was less than 50%.

Conclusion: The study showed that symptomatic individuals had a high degree of correlation with heterogeneous plaques on ultrasound. All heterogeneous lesions on MRI contained intra plaque blood with intracellular methemoglobin. Although MRI gives objectivity to the characterization of the plaque in both recent and remote strokes, ultrasound was found to be more sensitive for plaque disease <50% area stenosis.

Keywords: Carotid Plaque, Non contrast MRI, USG, Stroke Patients

Innovation

Stroke is a serious public health problem and the ischemic stroke accounts for the majority (80%) of all strokes. Atherosclerotic plaque at the carotid bifurcation is a major cause of ischemic strokes and the vulnerable plaque is associated with ischemic stroke more often than the non vulnerable plaque.

We have imaged carotid bifurcation plaque using US and MRI. These two modalities were used to evaluate 30 plaques each in recently and remotely symptomatic individuals. A comparative evaluation of these two modalities in the two groups of patients was done.

Study aimed to evaluate the imaging appearances of atheromatous plaque using Ultrasound and MRI and to evaluate the differences in imaging between recently symptomatic and remotely symptomatic plaques, Using ultrasound and MRI.

Material and Methods

This study was conducted at Command Hospital Air Force Bangalore over a period of 22 months from Nov 2009 to Aug 2011. A total of 60 lesions from cases of stroke and TIA who had come to receive treatment in our hospital were taken, which included both patients with both recent and remotely symptomatic ones.

Inclusion criteria

Only patients and control above the age of 20 were included in the study.
Recently symptomatic patients are those who have had an episode of ischemic stroke or TIA in the last 02 weeks. Remotely symptomatic patients are those who have had a history of ischemic stroke or TIA attack 3 months before.

**Exclusion criteria**
1. Patients who failed to meet the inclusion criteria
2. Patient in whom MRI is contraindicated
3. Patient who are claustrophobic and are afraid to undergo MRI
4. Patients who did not consent for the study.

**Imaging protocols**

**Carotid Ultrasound and Doppler**
The Ultrasound and doppler equipment available in the department was utilised- Siemens and GE pro logiq 5 with a linear probe with a frequency of 8–12 Mhz. The color doppler was used to assess the flow within the carotids and also helped in assessing the thickness of the plaque. The carotids were further analysed for their velocities as well as the area and diameter of stenosis.

**Interpretation of Data**
1. **B mode**
   - Plaque echogenicity is compared to the echogenicity of sternocleidomastoid muscle in the ultrasound examinations [Hypoechoic, Isoechoic and Hyperechoic, Calcification (Hyperechoic with shadowing)]
   - Maximal thickness of plaque
   - Maximal diameter of stenosis and maximal area of stenosis
2. **Doppler** (blood flow velocity at CCA, ICA and at max stenosis)

**MRI Scan**
It was done using class 1.5 Tesla scanner of Siemens (Avanto) and using neck coil with a single channel. Patient was explained the procedure and informed consent was taken. No special patient preparation was required (table-1, 2).

### Results

**Age Incidence**
The age of the subjects detected to have carotid bifurcation plaque, in this study ranged from 36 years to 78 years with a mean of 63.45 ± 10.22 years (Mean ± SD) The maximum incidence was noted in the 61-70 yrs age group.(41.7%) The age of the subjects with recently and remotely symptomatic lesions were within a range of 36 to 77 years, 38 to 78 years with a mean of 61.3 ± 9.8, 65.4 ± 10.3 years (Mean ± SD) respectively.

In our study, the maximum incidence of atherosclerotic plaque was between the age group of 61-70 yrs. Ultrasound, MRI and Plaque

The intimal thickness ranged from 1.1mm to 5.6 mm with a mean of 2.97 mm.

The range of area stenosis in recently and remotely symptomatic lesions had a mean of 41% and 50% respectively.

In our study, out of the 60 lesions, heterogeneous plaques were associated with symptomatic lesions in 65 % and homogeneous plaques were seen in 35 %. Calcification in the carotid bifurcation plaque was not visualized in any of the 60 lesions.

In our study, we were not able to detect the fibrous cap as a separate region of the plaque. Also we did not come across any lesion with surface irregularity suggestive of plaque rupture.

There were 17 (28.3%) plaques that were homogenous both on ultrasound and MRI. There were 12 (20%) plaques appeared heterogeneous on both ultrasound and MRI constituted 20.0%. Thus only 48 % of patients showed concordance between US and MRI in regards to homogeneity of the plaque.

More lesions appeared heterogeneous on ultrasound; however the content of these plaques and the stage of blood within the plaque as intracellular methemoglobin could be analyzed only on MRI.

In our study the imaging with gradient recalled image showed poor spatial resolution and the identification of hemorrhage or calcification within the plaque by detecting the contents.

**Table-2:** Identification of contents of plaque using both Ultrasound and MRI. ↓ - Hypointense/Hypoechoic ↑ - Hyperintense/hyperchoic
magnetic susceptibility artifact was difficult. It may be due to susceptibility to patient motion, overlapping with the jugular vein, and inability to image carotid stenosis and plaque morphology accurately due to turbulence on GRE images. In our study we were not able to identify the fibrous cap or its rupture in any of the lesions either on US or MRI. In our study, the lesions seen in both the sub sets, recently and remotely symptomatic lesions, the plaque morphology was the same and no statistically significant change was noted.

Both recently and remotely symptomatic patients showed heterogeneous lesions more frequently than homogenous lesions. The content of this heterogeneous plaque was intracellular met hemoglobin in all cases which were analyzed on MRI. The heterogeneous lesions were better visualized on ultrasound as compared to MRI. However the content of these plaques as intracellular met hemoglobin was analyzed only MRI.

**DISCUSSION**

Stroke is a serious public health problem in India and Ischemic stroke accounts for the majority (80%) of all strokes. Atherosclerosis is a type of arteriosclerosis derived from the Greek words “atheros” meaning “gruel” and “sclerosis” meaning “hardening” and is characterized by intimal lesions called atheromas that protrude into vascular lumina. It is synonymous with atheroma and atheromatous plaque. Imaging wise plaque is defined as a local thickening of the intimal layer of greater than 1 mm. The increased mechanical stress due to high flow velocity in patients with stenosis might lead to intraplaque hemorrhage with subsequent stretching of the intima over the hemorrhage with further turbulent flow and precipitate formation of luminal thrombi or lead to ulceration of intima that stretches over the hemorrhage, all possibly reducing cerebral blood flow by hypo perfusion or embolisation leading to – stroke or transient ischemic attack.

Typical atheromas contain relatively abundant lipid. However, fibrous plaques are composed mostly of smooth muscle cells and fibrous tissue. In advanced atherosclerosis, the fatty atheroma may be converted to a fibrous scar. The complicated lesion of atherosclerosis, defined by the following changes, has the most clinical significance. Focal rupture or gross ulceration or both, of the luminal surface of atheromatous plaques may result in exposure of highly thrombogenic substances that induce thrombus formation (cholesterol emboli or atheroemboli).

- Haemorrhage into a plaque occurs from rupture of either the overlying fibrous cap or the thin walled capillaries that vascularise the plaque.
- Superimposed thrombosis usually occurs on disrupted lesions (those with rupture, ulceration, erosion or hemorrhage).
- Thrombi may partially or completely occlude the lumen; they may become incorporated within the intimal plaque by organization.

**Carotid artery evaluation using Doppler ultrasound**

Zweibel WJ et al, prospectively studied carotid bifurcation and suggested that Doppler and B-mode combined were more accurate than separate use of either procedure for evaluation of occlusive lesions and the level of accuracy in evaluating plaque and stenosis provided a general estimate of severity of disease.

Imparto et al carried out a prospective study on carotid artery plaques which indicated that intramural haemorrhage was the only morphologic characteristic significantly more frequent in symptomatic plaques.

In 1983, Reilly et al, in their study concluded that the heterogeneous plaque was associated with a statistically greater incidence of plaque hemorrhage and ulceration and was associated with a greater incidence of transient ischemic attack or stroke.

In 1993 Geroulakos et al defined plaques into five types which was adopted and modified by AHA.

Type 1 plaques consisted of uniformly echolucent plaques,
Type 2 plaques consisted of predominantly echolucent plaques with <50% echogenic areas,
Type 3 plaques consisted of predominantly echogenic plaques with >50% echogenic areas,
Type 4 plaques consisted of uniformly echogenic plaques and
Type 5 plaques were those that could not be classified owing to heavy calcification and acoustic shadowing.

The results of a study showed that type 1 plaque was present in 5% of patient with symptoms and 95% in those without symptoms there was preponderance of echogenic plaques.

A study by El-Saden et al, stated that MRA - TOF and US could replace DSA if the studies were in agreement (100% sensitivity and 91% specificity with an accuracy rate of 94%), and concluded that agreement with MRA and US meant that further evaluation with DSA was unnecessary. In this study, the statistical analysis revealed, high sensitivities and specificities when using 3D TOF MRA (100% sensitivity and 91% specificity with an accuracy rate of 94%) but flow gaps resulted in accurate MRA examinations necessitating DSA in only a few patients.

Carotid plaque evaluation by Magnetic resonance imaging Kucharczyk et al in 1994 showed that calcified region of plaque consisted primarily of hydroxypapitate. Due to its low proton density and because of diffusion mediated susceptibility effects calcification was associated with low signal intensity on all the MR sequences.

In 1997 Yuan et al carried out in vitro study to differentiate different types of lipid using T1 weighted (T1W), T2 weighted (T2W) and proton density weighted (PDW) MR images. They showed that among individual lipids, triglycerides, which constituted 6% of the plaque, had strong signals in all three MR contrast weightings at body temperature.

In a study by Winn et al, a definite reading for detection of fibrous caps or rupture was fairly specific (90% and 98% respectively) but not very sensitive (37% and 12% respectively).

Yuan C et al carried on in vivo study on eighteen patients using 1.5TMR scanner that generated four contrast weighting (T1,T2, proton density and 3D time of flight). Overall accuracy of multispectral MRI was 87% (80% to
94%) sensitivity was 85% (78% to 92%) and specificity was 92% (80% to 98%).

High signal intensity on T2-SE images was characteristic of lipid, whereas low signal intensity on T2-SE images was characteristic of fibrous tissue. Yuan et al concluded that identification of a ruptured fibrous cap was highly associated with a recent history of TIA or stroke.

There was a strong and statistically significant trend showing a higher percentage of symptomatic patients with ruptured cap (70%) and thin cap (50%) compared with thick cap. Later in 2004 Chu et al found that MRI detected intraplaque hemorrhage with high sensitivity (90%) but moderate specificity (74%). Three stages of intraplaque hemorrhage were categorized: fresh, recent and old. In another study Kampschulte et al, found that the sensitivity and specificity of MRI to correctly identify cross sections that contained hemorrhage were 96% and 82% respectively.

Takaya et al, evaluation twenty nine subjects found that hemorrhage into carotid plaque produced a stimulus for progression of atherosclerosis by increasing lipid core and plaque volume and creating new destabilizing factors.

**Limitations of our study**

1. All patients were from service background – age bias, as people while in service are exercising regularly and hence reduced chances of plaque disease.
2. Only patients brought to the hospital were imaged – selection Bias as the hospital caters exclusively people from defence background and their families in and around the location. This does not represent the incidence in the local population.

**CONCLUSION**

In our study, a total of 60 lesions from symptomatic individuals were evaluated with ultrasound and MRI. The individuals were further divided into recently and remotely symptomatic. We had analyzed the morphological pattern of the plaque in these two sub sets with ultrasound and MRI and findings were further correlated.

Ultrasound was found to be more sensitive than MRI for plaque size < 1.5mm. Ultrasound was also better in assessing the plaque characteristics when the area of stenosis was less than 50%. Hence, ultrasound is better as a screening tool. The study showed that symptomatic individuals had a high degree of correlation with heterogeneous plaques on ultrasound with 66.7% recently symptomatic individuals showed heterogeneous plaques and the remotely symptomatic patient’s individuals had an association of 50% with a p value of 0.295.

The homogenous lesions on ultrasound appeared homogenous on MRI with the plaque content for fat. The heterogeneous plaque on ultrasound however was correlated in only 26% of the MRI. Out of the 39 lesions which appeared heterogeneous on ultrasound only 12 were found to be heterogeneous on MRI with a p value of 0.345. All heterogeneous lesions on MRI contained intra plaque blood with intracellular methemoglobin.

No cases had calcific plaque. Fibrous cap was not visualized in any of the cases in our study. A thinner slice with a smaller FOV could have helped in analyzing the fibrous cap. Although MRI gives objectivity to the characterization of the plaque in both recent and remote strokes, ultrasound was found to be more sensitive for plaque disease <50% area stenosis.
